

mmFace: 3D Face Recognition using RGB and Millimetre Wave Radar

Stergious Aji (2546916A)

April 7, 2024

ABSTRACT

Secure and compact face recognition systems often rely on expensive, non-commercial hardware that must be tailor-made for the specific application. Current systems typically employ near-infrared waves to capture detailed 3D maps of human faces due to its precision and dense outputs. However, this approach comes with certain limitations since they can be blocked by thin materials such as spectacles and facial hair. With the recent success of low-power millimetre wave sensors for hand gesture recognition, we investigate harnessing their ability to permeate fabric and hair for more resilient 3D facial recognition by integrating them with colour information. We propose mmFace, a hybrid end-to-end system using both RGB and mmWave face signatures that accurately classifies facial identities as well as detect their authenticity, effectively countering against 2D spoofing attacks.

1. INTRODUCTION

Facial recognition is a key area of research within the field of computer vision, finding extensive use across areas including human-computer interaction, security surveillance, and forensic analysis. Its primary application being biometric authentication, granting individuals access to their devices or restricted zones. This enables a non-intrusive, hands-free means of identity verification, eliminating the need to memorise passwords. Additionally, facial biometrics are naturally more attainable than other modalities such as fingerprints, palm prints, or iris scans [1].

Since its inception in the 1960s, facial recognition technology has undergone significant growth. Initially pioneered by Bledsoe [2], early systems distinguished faces by comparing manually annotated landmark features such as the nose, eyes, and mouth. More recently, the emergence of deep learning has amplified the performance of human face classification, benefitting from the vast online repositories of face images. Nonetheless, these systems predominantly rely on images captured by RGB cameras, leaving them vulnerable to variations in lighting and facial pose [3]. By incorporating depth data and drawing attention to the geometric details of the face, the impact of such environmental factors can be mitigated. Furthermore, the transition to three-dimensional facial recognition not only increases accuracy but also bolsters the security of biometric systems against spoofing attacks [4].

1.1 Motivations

The popularity of 3D face recognition is on the rise, evidenced by its adoption in smartphones with the likes of Apple and their Face ID [5] technology. This growing demand

has pushed the commercialisation of depth-sensing technology to smaller form factors, facilitating its efficient real-time operation on mobile devices [6]. Face ID, in particular, has garnered a level of security that enables payment authentication within services such as Apple Pay. However, Apple's use of costly proprietary hardware and restrictive patents make it harder for smaller companies to adopt an equally compact and secure face recognition system.

Depth cameras used in this context typically employ an active form of acquisition. This involves projecting non-visible light onto the face, which is then reflected back, allowing sensors to measure and map facial attributes. Lidar cameras, emitting waves in the near-infrared (NIR) spectrum, are the most prevalent choice given their capacity to acquire a dense 3D map of the subject's face [7]. However, they are often limited by their inability to penetrate thin materials such as clothing and hair. For instance, iPhone users must provide separate facial scans for scenarios involving spectacles or face masks to ensure Face ID operates effectively in all situations [8]. For instance, individuals must submit separate facial scans for when they wear spectacles or face masks in order for Face ID to operate in all scenarios. In contrast, millimetre wave radar (mmWaves) can penetrate such materials and directly reach the skin's dermal layer [9]. This could enable greater performance in scenarios involving facial hair or adverse environmental conditions such as rain or fog.

Research into the efficacy of radar waves for 3D face recognition remains relatively limited, although recent studies indicate promising outcomes [10, 11, 12, 13, 14]. Radar sensors typically offer greater cost efficiency in terms of both acquisition and computation, as they consume less power compared to NIR-based systems. Nevertheless, it is crucial to acknowledge the trade-off, as mmWaves often result in a sparser representation. This could impact recognition performance, where the precision in detecting and mapping facial features is paramount. Thus, we aim to counter-balance this limitation with the textural information gained from colour images, potentially paving the way for more resilient and versatile systems.

1.2 Research Contributions

Our work explores the effectiveness of using RGB cameras in conjunction with mmWave radar sensors for 3D facial recognition. Due to the absence of suitable datasets available for this purpose, we curated our own. We use the Intel RealSense L515 RGB-D camera [15] for photographing subject faces. Meanwhile, the Google's Soli 60 GHz radar sensor [16] is employed to gather depth information by transmitting

and measuring millimetre waves reflected from the target.

We have gathered face data from 21 participants under various conditions encompassing diverse poses, lighting settings, and common occlusion scenarios. This comprehensive approach led to a system that demonstrates robustness to environmental factors, surpassing systems reliant solely on RGB data.

We have developed a novel face recognition model using a convolutional-based neural network architecture that is able to encode identity-specific facial characteristics into a rich multimodal representation that incorporates both RGB and mmWave radar information. We investigate different feature fusion strategies in blending the two modalities, aiming to pinpoint the most effective strategy that provides distinctive embeddings for clean identity separation. The best performing model is benchmarked against prior radar-based facial recognition systems, as well as, a base comparison to using each modality independently.

The key contributions of this paper are summarised below:

- Compilation of a diverse face dataset comprising colour images and mmWave signatures from 21 participants. The dataset encompasses five different poses, two lighting conditions, and two occlusion scenarios.
- We present **mmFace**, a hybrid face recognition model that harnesses both modalities yielding a robust system capable of handling common occluding materials and nullifying 2D spoofing attempts. The model exhibits strong generalisation capabilities to unseen faces and discerns between live and fake faces effectively.
- An empirical analysis of seven feature-level fusion methods is conducted to determine the most optimal approach for blending RGB and mmWave facial features.
- Our models and evaluations are open sourced¹ to facilitate further research into small-scale, 3D face identification using mmWave technology.

2. BACKGROUND

2.1 mmWave Radar Technology

Radio Detection and Ranging, or Radar, has been around for decades and plays an instrumental role in fields including space exploration, aviation, and maritime navigation. Recently, the miniaturisation of radar sensors to operate in the millimetre wave band have expanded its applicability to more small-scale domains [6]. mmWave sensing has particularly excelled in the autonomous vehicle domain, facilitating object detection for systems such as collision warnings and adaptive cruise control [17]. This is primarily due to its edge over traditional lidar cameras, specifically in its resilience to atmospheric conditions such as dust, smoke, fog, and rain [18]. This penetrative power of mmWaves make it a promising candidate for reliable facial recognition in uncertain, real-world scenarios.

Another notable example is Google’s integration of their Soli sensor into the Pixel 4 smartphones for motion detection and gesture recognition [19]. However, the sensor’s potential application to face recognition remains unexplored, presenting a unique research opportunity. Consequently, this

¹<https://github.com/StergiouAji/mmFace-3D-Face-Recognition-using-RGB-and-mmWave-Radar>

is the sensor we use to capture mmWave face signatures during our data collection procedure. A key driving factor for this choice is the Soli’s miniature form factor of just $6.5\text{ mm} \times 5.0\text{ mm}$, and its use of Frequency Modulated Continuous Wave (FMCW) technology. This is proven to offer superior range resolution in comparison to other modulation techniques thanks to its high pulse compression [20], a vital aspect for extracting accurate facial features. Furthermore, The Soli chip has a relatively low power consumption due to the fact that it sends 16 chirps every burst at a pulse-repetition frequency of 2 kHz, after which it halts transmission until the next burst of chirps [21, 22]. Each burst is transmitted at rate of 25 Hz giving an overall transmission duty cycle of 2%. This effectively means that the radar chip remains inactive during the majority of its operation, saving a lot of power for small-scale mobile applications. x

2.2 Related Work

The use of millimetre waves for face identification is a relatively new avenue of research, fuelled by the recent commercialisation of radar sensor technology. One of the earliest studies delving into human identification using mmWaves dates back to 2019, conducted by Zhao et al. [23]. While this paper primarily examines the classification of subjects based on their gait and body shape rather than facial features, it underscores the capacity of mmWaves to capture the subtle idiosyncrasies among individuals. These nuanced differences are crucial for machine learning models to accurately distinguish between unique subjects, thereby yielding high class separations.

The following year, Hof et al. [10] introduces an autoencoder capable of recognising human faces captured by an 802.11ad/y networking chipset operating at a 60 GHz centre frequency (f_c). This autoencoder effectively encodes mmWave face signatures with sufficient distinction to discriminate between positive and negative instances based on their Mean Squared Error (MSE) against reference embeddings. The study involved an extensive data collection effort, capturing face scans of 206 participants of varying genders and ages, across five different poses: frontal, as well as head rotations of 15° and 25° to the left and right. This dataset was subsequently made available through an IEEE Data Port [24]. While this collection encompasses a wide range of faces, including some individuals with spectacles and beards and, it lacks representation of other common occlusion scenarios, such as head accessories, which our project aims to explore. Additionally, the study utilised a larger sensor with a total of 1024 transmit-receive antenna pairs, noted to capture redundant information. This contrasts with the compact Soli chip designed for integration within smartphones. The study simulated the impact of reducing the antenna count to 10, resulting in a significant decrease in the distinctiveness of facial signatures. Encouragingly, increasing the number of neurons in their Neural Network and adding an extra hidden layer could compensate for this loss.

Lim et al. [11] proposes a deep neural network with a more traditional Multi-Layer Perceptron (MLP) approach where every layer is fully connected to adjacent ones. The study utilised a small-scale, 61 GHz FMCW radar sensor developed by bitsensing Inc. [25], comparable to the Soli with a single transmit and three receiver antennas. The model attained a mean classification accuracy of 92% across eight subjects, surpassing the performance of both, a Support Vec-

tor Machine (SVM), and a tree-based Ensemble Learning approach trained on the same face signatures. It is important to note the relatively small-sized dataset used to train the model, raising concerns about potential overfitting as the data is not representative enough. The paper provides limited details on the data collection methodology used, only mentioning that the distances ranged from 30 cm to 50 cm. It can be assumed then that the study likely focussed on frontal poses without any occlusions for all eight subjects.

During the same time frame, Kim et al. [12] conducted research utilising an identical sensor from bitsensing Inc., which boasted a range resolution of 2.5 cm. Their study introduces a Convolutional Neural Network (CNN) model consisting of three convolutional layers and three fully connected layers. The radar data underwent extensive preprocessing to convert it into a format more akin to images, suitable for the CNN. With a data split of 70%/15%/15% for training, validation, and testing, the model achieved an average classification accuracy of 98.7% on a limited dataset of only three individuals. Notably, the study also investigated the impact of wearing cotton masks. The results indicated a negligible decrease in average classification accuracy by 0.9%, which bodes well for the goals of our project. Nonetheless, it is important to approach these findings with caution due to the small dataset size. It remains uncertain whether this level of performance would hold consistently across a larger group of subjects with more varied occlusions.

Pho et al. [13] adopts a One-Shot Learning approach to the problem. This is where the model is trained with a single or only a few labelled instances, beneficial when there is a lack of training samples available. The proposed method constitutes a Siamese structure of two identical CNNs with shared parameters, mapping the input radar signals into latent space. During both training and testing phases, a distance metric between the outputs of the networks is used to assess the similarity between face inputs. Specifically trained for binary classification, the model receives pairs of face signatures from either the same or different individuals. The same bitsensing Inc. BTS60 chipset, used by Lim et al. and Kim et al. [11, 12], is employed to capture 500 frames of the faces of eight participants. An average classification of 97.6% was achieved, an improvement over the previous deep MLP model by Lim et al. involving the same number of people. t-Stochastic Neighbour Embedding (t-SNE) [26] is then applied for dimensionality reduction. The resulting visualisations demonstrate that the one-shot Siamese network effectively separates each individual's face into exclusive regions, simplifying the classification task. Although a small dataset is used, only encompassing frontal poses with no occlusion settings, the proposed method is well documented and is likely robust against larger datasets.

Challa et al. [14] employs two different machine learning models on the dataset provided via the IEEE port [24]. Their approach began with CNN-based autoencoders, followed by a Random Forest Ensemble Learning approach. A total of nine autoencoders were built, each tailored to different frame rates, focusing on compressing and reconstructing the original data from its latent form. The autoencoders were trained using randomly selected data samples from a subset of 186 face scans. The flattened and labelled outputs were then used to train and test nine discrete Random Forest models using identical hyperparameters, as recommended by the Sci-kit library. This methodology yields im-

pressive results, achieving an average classification accuracy of 99.98% using all 1400 frames per individual. Even when reducing the number of frames to 70 per person, the model maintained a high accuracy of 97.1%. The paper presents an approach that is unique in comparison to the rest of the papers tackling this subject, showcasing an efficient model that is able to be deployed on mobile chips.

Research in this domain focuses exclusively on utilising data from radar sensors, largely driven by concerns surrounding privacy preservation. However, a significant drawback of this approach lies in the extended duration required to capture an accurate facial scan. The sensor typically needs to operate for several seconds, ranging between 10 and 15 seconds, to obtain a detailed scan. Such a time frame proves impractical in real-world scenarios, as it requires the subject to remain motionless for a prolonged period. Thus far, no study has explored the potential benefits of combining radar signatures with corresponding RGB data to enhance facial recognition capabilities. Given the high performance of existing deep learning models using RGB images alone, such as InsightFace [27], integrating them with mmWave radar data presents a promising avenue. This could expedite face acquisition time while capitalising on the advantages of mmWaves for environments where optical methods falter.

2.3 InsightFace

In the evolving field of face recognition, deep CNNs have emerged as a dominant approach due to their ability to automatically extract discriminative facial features from images. One significant advancement in this area is the InsightFace toolkit, implementing algorithms designed to address the intricacies of face analysis and recognition. Key works include the preliminary ArcFace model, introduced by Deng et al. [27], alongside the robust Face Alignment model by Gho et al. [28]. ArcFace employs a novel Additive Angular Margin Loss to maximise class separability, further enhancing the discriminative power in mapping face images to feature embeddings. However, this method was found to face challenges with label noise, requiring the “cleaning” of many real-world images sourced from the web. To address this, further progress was made with the Sub-center ArcFace model [29], introducing the concept of sub-classes to boost resilience against intra-class variations and label noise. It achieved state-of-the-art performance on many widely used benchmark datasets such as the Labeled Faces in the Wild (LFW) [30] and the YouTube Faces (YTF) datasets [31]. The integration of pretrained models offered by InsightFace into our system enables us to concentrate efforts on enhancing the performance of our model’s ability in extracting 3D structural information from mmWave face signatures.

2.4 Multimodal Data Fusion Methods

Multimodality, as defined by Lahat et al. [32], refers to the use and analysis of multiple types of data, potentially arriving from multiple sensors. The idea is to extract and blend salient information gathered by each sensor. The integration of this diverse data lead to outputs with richer representations than what could be achieved by the individual modalities alone.

One common strategy involves merging multiple data modalities before feeding them into a learning model, known as **Early Fusion** or **Data-level Fusion**. This technique entails

combining data by eliminating correlations between sensors or fusing data in a common, lower-dimensional space [33]. Methods like Principal Component Analysis (PCA) and Canonical Correlation Analysis (CCA) are frequently utilised for this purpose. However, a significant issue with early fusion is ensuring synchronisation between the RGB and radar frames, which is challenging due to their notably different sampling rates. Moreover, the continuous mmWave signals must be discretised to align with the format of the RGB data. An inherent drawback of early fusion is the potential to squash crucial information present within each individual modality, thereby impacting training effectiveness.

Late Fusion, or Decision-level Fusion, operates by independently processing distinct data sources through separate models and then integrating them at the decision-making stage. A common approach involves calculating a weighted average of the separate predictions, allowing a way to regulate the influence of specific modalities [34]. Late fusion is often simpler and more adaptable, proving effective when dealing with highly dissimilar data sources in terms of sampling rate, dimensionality, or units of measurement. Furthermore, late fusion often yields better performance since errors from multiple models are managed independently.

Intermediate Fusion, or Feature-level Fusion, is rooted in neural network architectures and revolves around the concept of combining different modalities within the feature space where there is a higher level of abstraction of the raw data. This can range from a basic concatenation of the individual latent embeddings to employing autoencoders for non-linear feature fusion, as demonstrated by Charte et al. [35]. This approach offers greater versatility than early and late fusions since it allows for the integration of features at various depths within the neural network. However, it can pose challenges such as the risk of overfitting or difficulty in learning relationships between the different modalities.

Each data fusion technique presents its own set of considerations, necessitating experimentation to determine the most effective approach to merging RGB and mmWave signatures. A variant of late, feature-level fusion, where the embeddings from the final layers of each model are combined, was chosen as the most feasible.

3. METHODOLOGY

3.1 Data Acquisition

Following a comprehensive research of the field, the subsequent steps involved planning and executing the data acquisition process required to train our proposed model. These experiments necessitated meticulous planning as the collected data directly determines the efficacy of the final model. As demonstrated by previous studies, it is crucial to compile multiple poses to enable the model to learn a complete 3D scan of the individual's face. Moreover, incorporating pose-invariance into the system is essential to accommodate real-world scenarios where individuals may not always present an exact frontal pose to the facial recognition system. Most studies focus on azimuth variations since individuals are less likely to tilt or pitch their heads by a significant amount. We similarly concentrated on head rotations around the yaw axis, deciding to capture facial poses at 0° , 30° , and 45° azimuth relative to the sensors.

Given that the experiment's objective is to explore the

advantages of mmWave sensors for face recognition, we included two distinct lighting conditions in our data collection trials: standard and low-light environments. Our hypothesis is that mmWave face signatures remain unaffected by ambient lighting since the sensor employs its own active illumination on the target face, unlike the RGB camera. Hence, if the system can achieve higher accuracy by incorporating both modalities rather than relying solely on colour, it would strongly indicate that mmWaves provide robustness against diverse lighting conditions.

Finally, we delve into assessing the permeating capability of mmWaves to directly reach the skin through fabric and hair by injecting typical occlusion scenarios into our experiments. It is advantageous for facial recognition systems to inherently withstand common obstructions such as glasses, hats, masks, and so on. Presently, users often need to remove such accessories for systems to accurately identify and grant access to specific devices or areas. With mmWaves, we speculate that this may not be required as facial features could be captured regardless. This could benefit security surveillance, especially in situations where individuals deliberately obscure their faces to conceal their identities. In our experiment, we capture scenarios both with and without occlusion. While cotton masks have been previously explored by Kim et al. [12], we incorporate other typical items such as sunglasses, hats, and scarves to mirror day-to-day use cases.

To ensure a diverse range of facial data, we recruited 21 participants within the limited time frame of the project. Adhering to ethical standards regarding sensitive personal information, our participant pool consists of male and female university students and faculty in the age range 18–35 years. A total of 15 scenarios are captured for each participant at a distance of 20 cm from the sensors. Each time the sensors are run for 10 seconds with the participant being asked to maintain a neutral expression, totalling 150 RGB frames and 3,750 mmWave frames per person. On top of this, scans of printed faces are also collected in order to train the model to detect facial authenticity as well as its identity. This was restricted to the three frontal poses for each participant, mirroring common spoofing tactics, providing another 30 RGB frames and 225 mmWave frames per fake instance.

A close-up of the equipment setup used can be observed in Figure 1 showing the Intel Realsense L515 RGB-D camera and the green Soli chip mounted side-by-side on a breadboard. The full experiment setup is photographed in Figure 2 with the red cross indicating the 20 cm face distance where subjects need to be positioned, and the five pose directions marked by the yellow tape.

Figure 1: Equipment: Intel Realsense L515 RGB-D Camera (left) and the Google's Soli 60 GHz radar sensor (right)

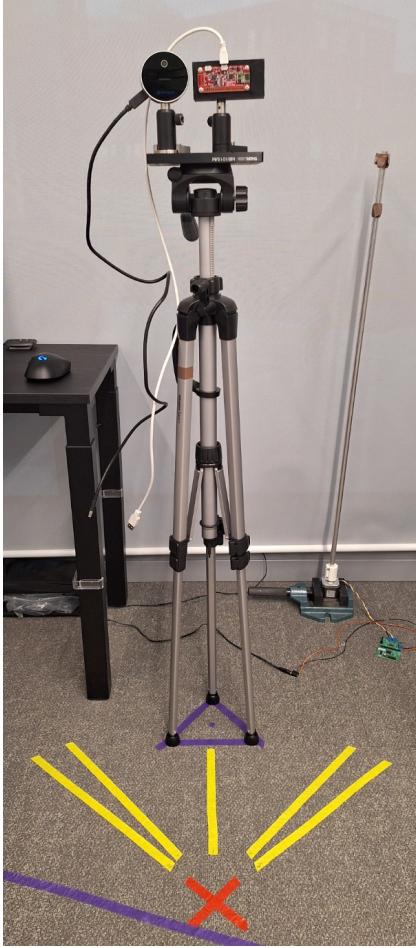

Figure 2: Experiment setup used for data acquisition with the equipment mounted on a tripod. The red cross marks the 20 cm face distance and the yellow tape indicates the five pose directions.

To illustrate the results of the collection process, the left half of Figure 3 presents data samples from a single subject. This grid shows RGB captures from all 15 scenarios, with the three different conditions along the rows and the five pose variations along the columns. For brevity, the experiment conditions are abbreviated as outlined in Table 1.

Abbreviation	Expanded Form
NO	No Occlusion
O	Occlusion
RLC	Regular Lighting Condition
DLC	Dim Lighting Condition

Table 1: Table displaying full forms for abbreviations describing experiment conditions.

The radar bursts acquired during the data collection phase undergo multiple FFT stages of preprocessing to convert the raw signals into discretised Complex Range-Doppler (CRD) maps. These maps offer a two-dimensional representation of the reflected radar signal, where the range dimension corresponds to the distance from the Soli sensor, and the Doppler dimension corresponds to the radial velocity of the subject towards the sensor [16, 21]. Face scans are obtained using the Soli’s short configuration, operating at an f_c of 60 GHz,

with a maximum bandwidth B of 5.5 GHz. This configuration provides a range resolution Δr of:

$$\Delta r = \frac{c}{2B} = 2.7 \text{ cm}$$

where c denotes the speed of light. The Soli chip comprises a single transmit and three receiver antennas, each capturing a superposition of scattered reflections from the target. Given that the Intel RealSense captures RGB-D frames at a different sampling rate of 30 frames per second (FPS), timestamp information is also logged for the potential of synchronising the two modalities for early data fusion. The right half of Figure 3 depicts a plot of a single CRD frame across the three receiving channels of the same subject’s face. The plot illustrates the discrete intensities of received signals across 16 Doppler bins along the x -axis and 32 Range bins along the y -axis.

3.2 mmFace

Building on the intuition from Section 2.3 of the Background chapter, it is clear that the ArcFace model from the InsightFace toolkit emerges as the best choice for our project. It attains state-of-the-art classification results on accepted benchmark sets, outperforming the previous bests such as Facebook’s DeepFace [36] and Google’s FaceNet [37]. This selection allows us to treat the RGB data processing as a **black-box** framework, enabling us to concentrate efforts on perfecting the radar-based feature extraction we are naming, **mmFace**. Furthermore, this facilitates exploration into the various methods in fusing the two modalities.

Figure 5 depicts a high-level diagram of the system workflow employed during training and inference. A more detailed architecture of our end-to-end **mmFace** model can be viewed in Figure 5 providing a comprehensive breakdown of each layer as well as their input and output channels. In summary, **mmFace** takes two inputs: an mmWave face signature in an ARD format and an InsightFace embedding extracted from the corresponding RGB frame. In order to simplify computation, the magnitudes of each complex value, encoding the range r and Doppler d bin, are derived to generate an Absolute Range-Doppler (ARD) map as follows:

$$\text{ARD}_{r,d} = \text{abs}(\text{CRD}_{r,d})$$

The inputs then go through three main stages: **mmWave Feature Extraction**, **Feature Fusion**, and **Class Prediction** each described in detail below to ultimately yield a subject and liveness detection. The liveness detection is a simple binary classification: 0 denoting a fake subject or 1 for real.

1. **mmWave Feature Extraction:** Firstly, the ARD input is processed through four unstrided convolutions followed by a max-pooling then two fully connected layers to compress the radar embedding vector.
2. **Feature Fusion:** The next phase involves fusing the extracted radar embedding with the RGB embedding input. This is modular in design in order to allow any compatible fusion strategy to be employed. This is then processed through a single fully connected layer to reduce its dimensionality before advancing to the final stage.
3. **Class Prediction:** Finally, the fused multimodal embedding is carried across two separate fully connected layers to predict the identity of the face and its authenticity which are subsequently outputted.

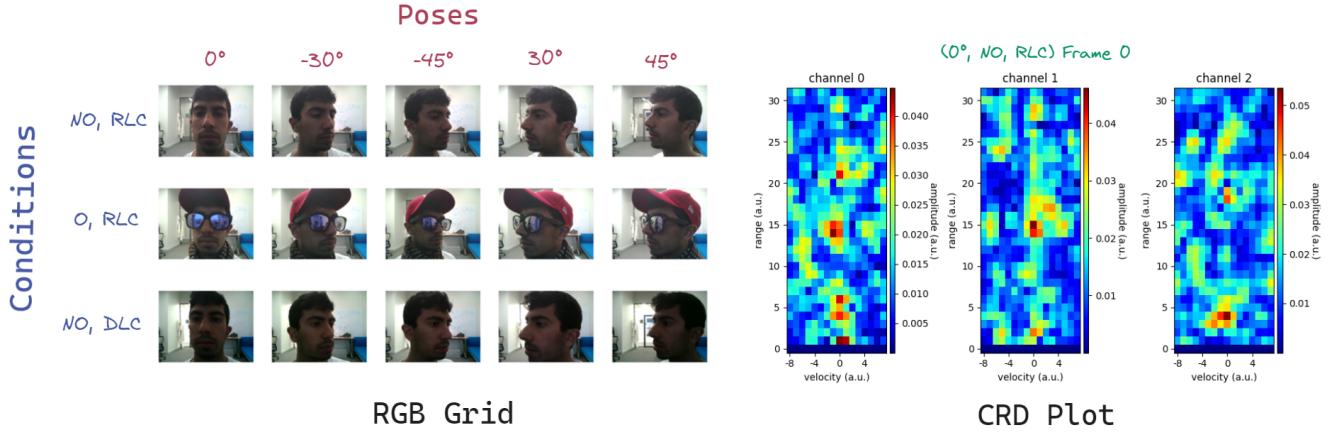

Figure 3: Data samples collected for Subject 0. The left figure shows the RGB frames of all 15 scenarios organised by pose and condition. The right figure plots a single CRD frame showing amplitudes of reflected waves detected by the three receiving channels of the Soli, categorised into discrete Range-Doppler bins.

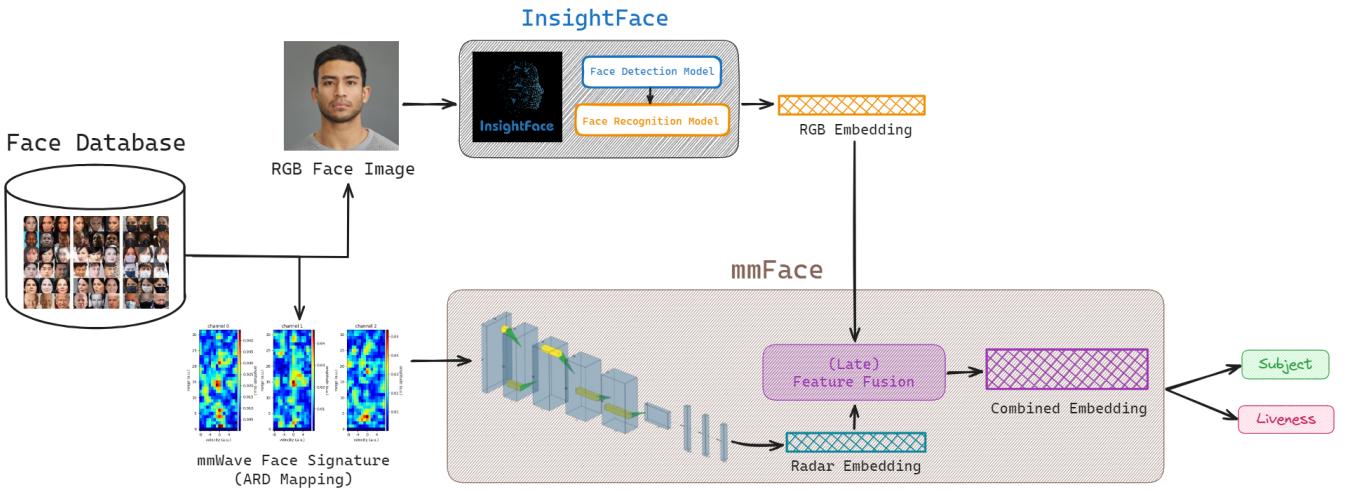

Figure 4: High-level model workflow diagram of our proposed 3D face recognition system incorporating millimetre-wave radar and RGB images.

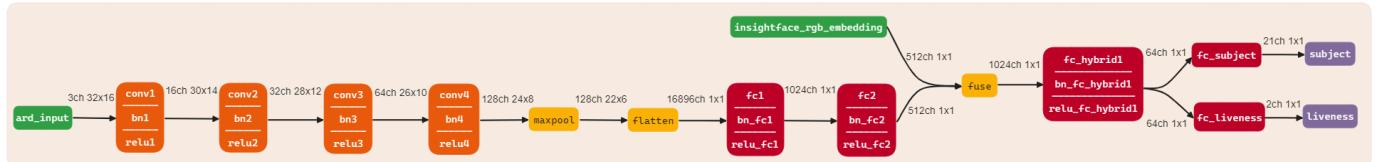

Figure 5: Model architecture of our mmFace model displaying each layer, as well as its input and output sizes.

The three-channel ARD format of the mmWave face signatures allows leveraging convolutional-based feature extraction due to its image-like structure. Convolutional layers would be able to detect spatial patterns among the range and Doppler profiles specific to individual faces, with potential enhancement through deeper layers. Due to the relatively small size of the ARD maps only being 32×16 bins per channel, it was imperative to preserve most of the information, minimising the need for additional max-poolings or strided convolutions. To streamline the fusion stage, we decided to match the final radar embedding size with the

512-dimension InsightFace feature vector. Four convolution layers with a 3×3 kernel size and filter sizes sequentially increasing in powers of two starting from 16 to 128 were found to be sufficient, with additional layers affording diminishing returns. All linear transformations are followed by batch normalisation layers to reduce overfitting and increase the generalisability of the model. ReLU activations are chosen for all non-linear transformations to prevent vanishing weights.

We opted to focus on mixing the two modalities within the feature-space, specifically within the network's final lay-

ers. This facilitates an easier fusion process since the data from both modalities are abstracted into a compressed representation. Pure intermediate fusion was not feasible due to the black-box treatment of the InsightFace model making it difficult to integrate information from within its hidden layers. Early fusion presents hurdles as well due to the dissimilarities in sampling rates and data formats. The ARD maps have to be synchronised and transformed into a depth image. This is an interesting avenue left to be explored possibly training a neural network to transform the radar bursts into pixel-wise point cloud.

Data augmentations are applied to both ARD and RGB frames, restricted to horizontal and vertical flips due to the distinct nature of both modalities. Augmentations were carefully selected to be semantically consistent across the layout of the mmWave face signatures and colour images. Rotational augmentations, for instance, cannot be seamlessly translated into the range and Doppler bins of the ARD as is the case with traditional images. Data augmentations aimed to introduce positional equivariance and inflate the small dataset size to learn to recognise facial features consistently across different instances.

Ultimately, `mmFace` contains around 2.8 million parameters and takes, on average, 4.1 milliseconds (SD = 0.2 ms) to process a single (`ARD`, `RGB_embedding`) input pair on an NVIDIA GeForce GTX 1650 GPU.

3.2.1 Training

We created and trained our models using PyTorch version 2.1 [38], running for 20 to 25 epochs, employing a Stochastic Gradient Descent (SGD) optimiser that was tasked with minimising the cross entropy losses (L_{CE}) of each prediction. We opted for a fixed learning rate of 0.01, an L2 regularisation rate of $1e-3$, and a momentum of 0.9. As our model generates two predictions, we merge the losses from each with equal weighting to ensure uniform learning of both attributes. This combined loss \mathcal{L} is formulated as follows:

$$\mathcal{L} = L_{CE}(s, \hat{s}) + L_{CE}(l, \hat{l})$$

Here, s and l represent the true subject and liveness labels, respectively, while \hat{s} and \hat{l} signify the model's corresponding predictions.

We train our models on a random subset of 17 out of the total 21 subjects, which accounts for just over an 80% training split, noting that this includes the 17 fake counterparts, giving 34 total subject instances. The remaining four subjects (or eight instances) are left out for testing.

3.2.2 Testing

Our models are evaluated through a zero-shot classification task in order to assess the generalisation ability at identifying unseen faces. During inference, the features from the final hybrid fully connected layer, `fc_hybrid1`, are used. The cosine similarity between the final embedding of each test instance and eight pre-selected reference embeddings are calculated to find the maximal score and corresponding prediction for face identity and liveness. A decision threshold t is used such that the maximal score must be greater than it to qualify for a valid prediction. This ensures that predictions are not made for output embeddings that are mostly equidistant to all reference embeddings or too far such that no practical decision can be made.

3.3 Feature-level Fusion

We investigate seven feature-level fusion strategies listed as follows in terms of two n -dimensional feature vector inputs, $\vec{x} = [x_1, x_2, \dots, x_n]$ and $\vec{y} = [y_1, y_2, \dots, y_n]$:

- Concatenate:** This is a straightforward concatenation of the two feature vectors, the most common strategy employed for its ease of implementation and effectiveness as all information is preserved.

$$\text{concatenate}(\vec{x}, \vec{y}) = [\vec{x}, \vec{y}]$$

- Add:** This involves an element-wise vector addition of \vec{x} and \vec{y} . This can be highly effective when both feature vectors point in the same direction compounding their resulting summation, however, if both feature vectors point in opposite directions, then this would result in a more orthogonal resulting vector direction.

$$\text{add}(\vec{x}, \vec{y}) = [(x_i + y_i) \mid \forall i \in \{1, \dots, n\}]$$

- Hadamard Product:** This is the element-wise vector multiplication or the Hadamard product of \vec{x} and \vec{y} . The idea here is to preserve the original feature vector structure while emphasising relationships between corresponding feature elements. It has been used successfully for multimodal residual learning by Kim et al. [39].

$$\text{hadamard_product}(\vec{x}, \vec{y}) = [(x_i y_i) \mid \forall i \in \{1, \dots, n\}]$$

- Pairwise Dot Mean:** This involves a dot product of the transpose of vector \vec{x} with vector \vec{y} resulting in an $n \times n$ matrix followed by a column-wise mean operation to produce an n -dimensional fused feature vector. The rationale behind this stems from the pairwise dot providing a more comprehensive blending of the feature. Each radar feature is multiplied by every RGB feature, and the resulting values are all attended to during the pooling process to reduce the dimensionality of the matrix.

$$\text{Let } \mathbf{Z} = \vec{x}^T \cdot \vec{y} \text{ in}$$

$$\text{pairwise_dot_mean}(\vec{x}, \vec{y}) = \left[\frac{1}{n} \sum_{j=1}^n \mathbf{Z}_{j,i} \mid \forall i \in \{1, \dots, n\} \right]$$

- Pairwise Dot Max:** This similarly involves the dot product followed by a column-wise max. In contrast to averaging, which could squash certain feature correlations, this approach isolates larger features resulting from the exhaustive mixing of both modalities, a similar intuition behind the max-pooling layers. Here, $*$ denotes a selection of all rows of a matrix.

$$\text{Let } \mathbf{Z} = \vec{x}^T \cdot \vec{y} \text{ in}$$

$$\text{pairwise_dot_max}(\vec{x}, \vec{y}) = [\max(\mathbf{Z}_{*,i}) \mid \forall i \in \{1, \dots, n\}]$$

- Pairwise Dot Flatten:** This is the final pairwise dot fusion strategy now following the dot product with a flatten operation of the $n \times n$ matrix into an n^2 -dimensional vector. This conversely retains all correlations between the radar and RGB features, leaving the subsequent fully connected layers of the model to determine which features are most relevant.

$$\text{Let } \mathbf{Z} = \vec{x}^T \cdot \vec{y} \text{ in}$$

$$\begin{aligned} \text{pairwise_dot_flatten}(\vec{x}, \vec{y}) &= \\ &[\mathbf{Z}_{1,1}, \mathbf{Z}_{1,2}, \dots, \mathbf{Z}_{n,n}, \mathbf{Z}_{n,n}] \end{aligned}$$

7. Multi-Head Attention: This involves using a self-attention mechanism prevalent in transformer architectures popularised by the seminal paper by Vaswani et al. [40]. It was initially designed for natural language processing tasks but has shown a lot of success in computer vision. The key idea of self-attention is to isolate and mix the most important aspects from both feature vectors by converting them into three distinct representations: a query \mathbf{Q} , key \mathbf{K} , and value \mathbf{V} . Each embedding plays a unique role such as the query capturing features that the model deems relevant for making predictions. To do this \mathbf{Q} may focus on features that are shared or discriminative across both modalities such as facial landmarks and overall identity information. Meanwhile, \mathbf{K} might focus on modality-specific elements such as the colour and texture information embedded within the RGB feature vector, while 3D structural details being offered by the radar embedding. Finally, \mathbf{V} encapsulates the actual fine-grained details captured by both modalities that will be attended to by the model based on the resulting query-key similarities. In order to maximise this effect, this mechanism is applied separately across multiple attention heads, reducing the risk of overlooking salient characteristics. This is expressed formally below, where first the two inputs are stacked vertically, $\mathbf{X} = \begin{bmatrix} \vec{x} \\ \vec{y} \end{bmatrix}$, then copied through three separate linear transformations to obtain the \mathbf{Q} , \mathbf{K} , \mathbf{V} matrices. This is done for each of the k attention heads using separate learnable weight matrices.

$$\begin{aligned} & \text{Let } h_i = \text{Attention}(\mathbf{Q}_i, \mathbf{K}_i, \mathbf{V}_i) \text{ in} \\ & \text{multihead_attention}(\vec{x}, \vec{y}) = [h_1, \dots, h_k] \mathbf{W}^O \\ & \text{where } \mathbf{Q}_i = \mathbf{W}_i^Q \mathbf{X}, \mathbf{K}_i = \mathbf{W}_i^K \mathbf{X} \text{ and } \mathbf{V}_i = \mathbf{W}_i^V \mathbf{X} \end{aligned}$$

4. EVALUATION

We evaluate our model by examining its discriminative ability at representing the four unseen faces. We utilise various metrics, such as the prediction accuracies, precision, recall, and ROC AUC, to compare the different fusion strategies against each other as well as showing their performance against simply using the individual modalities. Prior to the zero-shot task, we select and extract the final hidden layer of eight reference frame pairs. These reference embeddings serve as the basis for comparison against the rest of the test set, encompassing both live and fake samples of the four unseen subjects. The references were picked out of the frontal pose, non-occlusion, and regular lighting category as this is the most common setting for face recognition tasks.

4.1 Results

Firstly, we gauge the accuracies of the models in predicting both the facial identity and authenticity. This involves determining the most similar reference embedding to the final feature vector of a specific test sample using the maximum cosine similarity. A decision threshold t of 0.5 is applied to quantify a true prediction, otherwise, it is marked as a failed prediction. All models demonstrate high coverage, as illustrated in Table 3, with the radar-only model achieving the lowest coverage at 79.8%. Secondly, since the eight selected reference instances exhibit two properties – facial identity and liveness status – this allows for the calculation

of separate metrics to assess each model’s ability to predict identity independently of the liveness check.

4.1.1 Zero-shot Accuracies and F-measures

Table 2 presents the subject and liveness accuracies for all feature fusion strategies as well as the weighted F_β -measures, averaged over all the respective classes. For completeness, the performance of the individual modalities are also listed in order to show the advantageous effect of the multimodal feature fusions. A β value of 0.5 was chosen for the F-scores since, in face recognition systems, erroneously admitting the wrong identity is more detrimental than false negatives, thus requiring twice the emphasis on precision compared to recall.

Fusion Strategy	Subject		Liveness	
	Accuracy (%)	$F_{0.5}$ Score	Accuracy (%)	$F_{0.5}$ Score
Concatenate	83.7	0.835	99.6	0.996
Add	63.0	0.629	99.2	0.992
Hadamard Product	87.1	0.869	96.7	0.963
Pairwise Dot Mean	88.8	0.880	80.8	0.808
Pairwise Dot Max	82.7	0.820	72.8	0.735
Pairwise Dot Flatten	86.7	0.862	94.7	0.944
Multi-Head Attention	86.3	0.851	96.4	0.950
Radar Only	38.2	0.370	96.6	0.916
RGB Only	85.5	0.855	69.3	0.701

Table 2: Subject and liveness accuracies and weighted-averaged $F_{0.5}$ measures for the seven feature fusion strategies along with the individual modalities.

The best and worst performers are highlighted in green and red respectively. Evidently, certain fusion strategies excel at identifying subjects, while others are more adept at predicting face liveness. Among these strategies, the concatenation method emerges as the most effective for accurately verifying liveness. Meanwhile, the pairwise dot then mean strategy outperforms within the subject category, attaining the highest accuracy and $F_{0.5}$ measure. However, it’s ability to detect face liveness is notably lacking, obtaining an accuracy that is even lower than simply using the mmWave radar features. This is likely due to the mean pooling step squashing outlier feature correlations between the two modalities that may be relevant for the liveness detection. The vector addition proves to be very ineffective in predicting facial identity, being much better at predicting liveness in comparison.

Examining the individual performance for each prediction type provides insight into the strategies’ effectiveness in classifying unseen data to their respective labels. However, it’s equally important to identify the overall best strategy that performs well in both categories.

Fusion Strategy	Mean Accuracy (%)	Mean $F_{0.5}$ Score	Coverage (%)
Concatenate	91.7	0.915	99.7
Add	81.1	0.811	99.9
Hadamard Product	91.9	0.916	98.1
Pairwise Dot Mean	84.8	0.844	95.3
Pairwise Dot Max	77.8	0.778	95.6
Pairwise Dot Flatten	90.7	0.903	97.8
Multi-Head Attention	91.3	0.900	92.5
Radar Only	67.4	0.643	79.8
RGB Only	77.4	0.778	97.5

Table 3: Averaged accuracy and $F_{0.5}$ score for the seven fusion strategies and individual modalities, applying equal weighting to subject and liveness predictions.

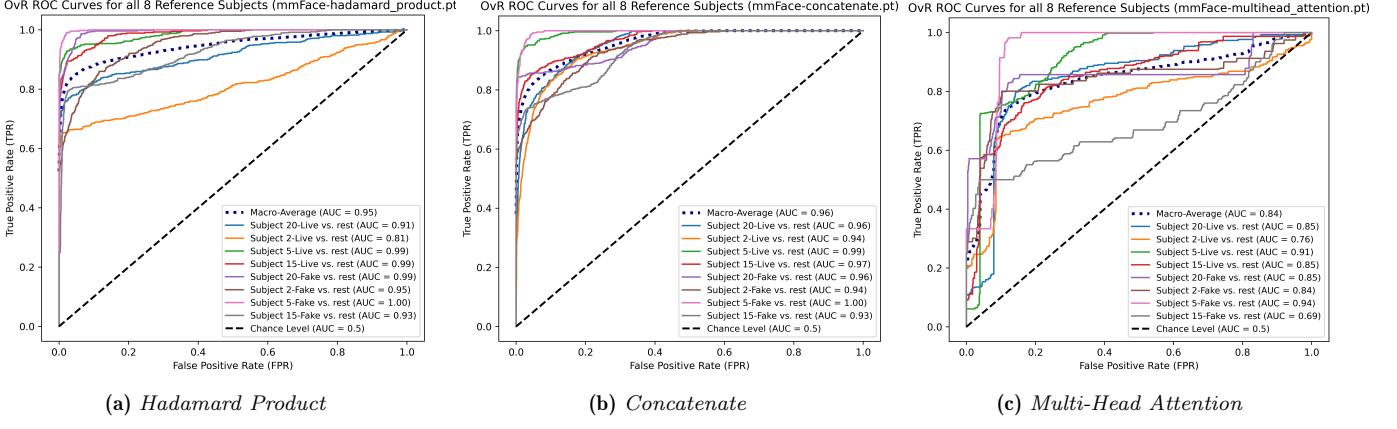

Figure 6: One-vs-the-Rest ROC curves plotted for each of the eight reference embeddings. Their respective AUC metrics are shown as well as the chance level and macro-averaged ROC curve. The sub-figures show the top three overall ranking models.

Table 3 showcases each of the nine models with their respective average accuracy and $F_{0.5}$ measure applying equal weighting to the subject and liveness results. It is evident that the Hadamard product of the two feature vectors achieved the highest mean accuracy and F-measure. Additionally, it highlights the fact that all fusion strategies improve on the results from using the independent modalities alone. On average, the fusion strategies exhibit a 9.6% improvement in mean accuracy, relative to the RGB-only model which obtained the highest accuracy out of the two non-hybrid models.

4.1.2 ROC Curves and AUC

Despite the positive aggregated results, it is worth noting that the element-wise product method is closely followed by the concatenation and multi-head attention strategies. Hence, it can be more useful to assess the model’s performance at different decision thresholds to provide deeper insights into which strategy yields the better classifier. This is the main idea behind the Receiver Operating Characteristic (ROC) Curve which analyses the sensitivity or true positive rate (TPR) against the false positive rate (FPR) at varying decision thresholds. Given the multi-classification nature of our task, the One-vs-the-Rest (OvR) ROC curve is the most appropriate. Here each class is evaluated against the rest using a one-hot strategy. This, therefore, requires each of the eight reference test instances to be plotted separately.

Figures 6a, 6b, and 6c plots the one-vs-the-rest ROC curves for the three highest overall performing strategies – namely the Hadamard product, concatenation, and multi-head attention, respectively. The blue dotted curves indicate the macro-averaged trend among the individual OvR curves, while the dashed diagonal line denotes the chance level equivalent to a random guessing model. Curves above the chance level and reaching the top-left corner demonstrate a better classifier. This is often quantified by the area under the ROC curve (AUC) metric.

Table 4 lists the macro-averaged AUC metrics for all nine models. As made evident from both the table and plots, while the Hadamard product offers the highest accuracies it does not maintain its predictive nature across all decision thresholds attaining an AUC of 0.945. While this is relatively, it is overshadowed by the 0.961 AUC achieved by the concatenation strategy which ranked second-highest

within the overall performance. Figure 6b show that the concatenation method performs equally well at distinguishing the majority of the reference instances since all curves are tightly packed and in close proximity to the top-left corner. In contrast, the ROC curves for the Hadamard product method are more dispersed with the relatively low distinguishing ability for the class *Subject 2-Live*. The disparate OvR ROC curves for the multi-head attention fusion strategy in Figure 6c suggest that it does not generate embeddings as robust as those of the other two strategies, with a proportionally higher number of false alarms compared to true positives for certain outlier classes.

Fusion Strategy	Macro-Averaged AUC
Concatenate	0.961
Add	0.918
Hadamard Product	0.945
Pairwise Dot Mean	0.914
Pairwise Dot Max	0.863
Pairwise Dot Flatten	0.925
Multi-Head Attention	0.913
Radar Only	0.735
RGB Only	0.901

Table 4: Table listing the macro-averaged AUC metrics for all fusion methods as well as the individual modalities.

4.1.3 t-SNE Visualisations

Following this, it is important to visualise the final embedding vectors of each model to verify that each identity is pushed to distinct regions of the high-dimensional Euclidean space. *t*-distributed Stochastic Neighbour Embedding or t-SNE [26] is commonly employed to reduce the dimensionality of feature vectors to a lower space. t-SNE tends to preserve the local structure of the data much better in comparison to Principal Component Analysis (PCA) which is better at retaining the global variance in the data. This means that t-SNE can help identify meaningful patterns or groupings within the data since the similarities between data points are maintained providing interpretable visualisations.

Figures 7a, 7b, and 7c depict the final features extracted from the top three overall ranking strategies after t-SNE. Each data point is colour-coded by the subject identity,

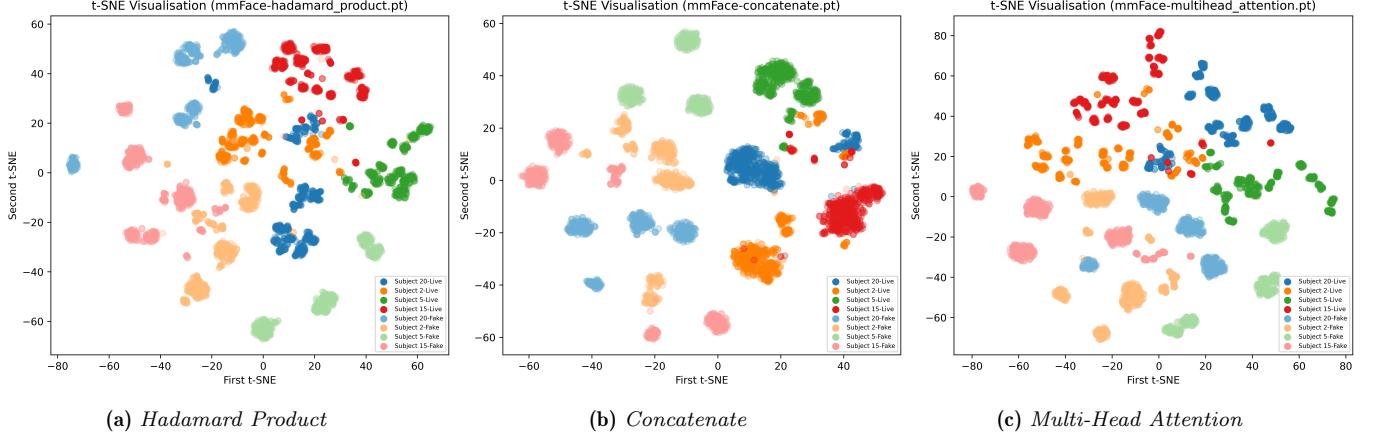

Figure 7: 2D t-SNE projections of the final layer features of the top three overall ranking fusion strategies. Features extracted from the `fc_hybrid1` layer of each model.

with those originating from fake instances shown in a lighter shade. It is clear that all three strategies group facial data from the same subject into similar regions of the multimodal space. It can be observed that fusion by concatenation results in a tighter clustering with greater separation between the distinct grouped islands of data points. Additionally, it can be seen that some data points overlap with non-similar clusters in each of the strategies, with the least confusion being observed within the Hadamard product visualisation. This explains the higher subject recognition accuracy being attained in comparison to the concatenation and multi-head attention strategies. Nonetheless, the concatenation strategy produces a clear linear separation between fake and real faces, providing rationale for its achievement of the highest liveness detection accuracy at 99.6%. The other two strategies do not produce such a clear separation, requiring more complex, non-linear boundaries.

It is evident that there is more noise among the features from the real dataset compared to the fake, producing more erratic clusterings and confusion among all three strategies. This can be attributed to the higher level of variation of poses among the real dataset in contrast since only the frontal poses were utilised for the fake dataset. Furthermore, so far the models have been assessed from a general perspective, treating all conditions equally. However, it is just as important to examine the performance of the models under the specific conditions, such as dim lighting and occlusion settings, in isolation.

4.2 Dim Lighting Condition

First, the dim lighting condition experiments are isolated and compared against the non-occluding captures under regular lighting. For brevity, Table 5 shows the mean accuracy and weighted F-measures for each of the nine models, assigning equal weight to subject and liveness predictions. Nonetheless, the findings suggest only a marginal decrease of 0.43% in subject accuracy, on average, in comparison to regular lighting condition captures. Interestingly, the dim lighting setting produces a slight increase in liveness accuracy, averaging 0.2% across all fusion strategies. This is most likely due to the reduced sample size amplifying the impact of outlier results.

This time the multi-head attention strategy emerges as

Fusion Strategy	Mean Accuracy (%)	Mean $F_{0.5}$ Score	Coverage (%)
Concatenate	90.4	0.903	99.9
Add	85.5	0.862	100.0
Hadamard Product	88.9	0.886	96.8
Pairwise Dot Mean	82.8	0.825	96.0
Pairwise Dot Max	79.8	0.792	93.2
Pairwise Dot Flatten	90.7	0.906	98.5
Multi-Head Attention	91.1	0.902	95.7
Radar Only	67.2	0.636	80.1
RGB Only	82.0	0.811	92.7

Table 5: Averaged accuracy and $F_{0.5}$ score for the seven fusion strategies and individual modalities against the **dim lighting** settings only. Equal weighting is applied to subject and liveness predictions.

the overall top performer, although it still exhibits a low coverage giving the pairwise dot then flatten method a slight edge. A more interesting observation arises with the RGB-only model, leveraging solely on the 2D InsightFace embedding. It achieves a relatively high $F_{0.5}$ measure of 0.821 for recognising subjects, contrary to our initial hypothesis. While it was anticipated that the RGB-only model would suffer under dim lighting, it still manages to outperform the radar-only model. Ignoring the small sample size, it is worth noting that the dim lighting environment was not controlled as rigorously with a fixed lumen rating. Instead, it was achieved through the lowest light setting of the experiment room and closed shades. Additionally, variations in ambient lighting from the sun at different capture times were not accounted for. It's evident that a more extreme condition is necessary to fully assess the impact of ambient lighting on RGB captures and the robust InsightFace model.

4.3 Occlusion

Next, the captures incorporating day-to-day occlusion scenarios where participants were asked to wear hats, sunglasses and scarves. To minimise the risk of the model learning to segment specific colours or shapes, several types of hats were utilised including different coloured baseball caps and beanies. All sunglasses used included a mirrored lens such that the participant eyes could not be seen by the RGB camera. Moreover, the participants were instructed to wear the accessories as they naturally would, providing more variations within the dataset.

Table 6 presents the aggregated findings for all nine models, similarly applying equal weighting to subject and liveness measures. Evidently, there is a 3.9% decrease in subject classification accuracy and a 1.7% decrease for liveness detection, averaged across all seven fusion methods, compared to the non-occlusion scenarios. However, it can be asserted that this decline is due to the less discriminative RGB features, as evidenced by the radar-only model’s improved performance in both categories over the general performance. The radar-only model achieves 42.3% at identifying the unseen subjects with occlusion and a liveness detection rate of 99.3%, beating the RGB-only model’s scores. This aligns with our hypothesis that mmWaves, with their ability to permeate through fabric to directly reach the dermal layer of the skin, could offer robustness against occluding materials. However, this warrants verification with a bigger participant pool and even more diverse occluding accessories to say with confidence.

The concatenation arises as the outperforming strategy surpassing other strategies by over 6.8% in mean accuracy, on average. This is mainly attributed to its high liveness detection accuracy of 99.5%. Impressively, it is still able to cover a significant proportion of the data subset, achieving a 99.7% coverage rate, exceeding even the individual modality coverage rates.

Fusion Strategy	Mean Accuracy (%)	Mean $F_{0.5}$ Score	Coverage (%)
Concatenate	91.4	0.911	99.7
Add	78.8	0.781	99.2
Hadamard Product	88.4	0.829	93.8
Pairwise Dot Mean	82.4	0.764	92.6
Pairwise Dot Max	77.6	0.710	91.5
Pairwise Dot Flatten	88.7	0.871	98.2
Multi-Head Attention	82.5	0.813	98.5
Radar Only	70.8	0.713	82.7
RGB Only	68.6	0.682	80.7

Table 6: Averaged accuracy and $F_{0.5}$ score for the seven fusion strategies and individual modalities against the occlusion scenarios only. Equal weighting is applied to subject and liveness predictions.

4.4 Discussion

Taking all findings into account, it is safe to conclude that the concatenation strategy yields the best performing model, especially excelling in detecting facial authenticity. It attains second-highest in the aggregated overall metrics, third-highest in the dim lighting setting, and top-ranking in the occlusion only scenarios. On top of this, the concatenation fusion strategy produces the most distinctive final feature embeddings with clear separations between facial identities as well as liveness in the t-SNE plots. This is also evidenced by the method achieving the highest macro-averaged AUC with a much greater sensitivity rate over false alarm across all decision thresholds.

There were three total candidates for the best fusion strategy, but the concatenation came out on top due to its higher coverage rate than both the Hadamard product and the multi-head attention mechanisms. The Hadamard product is a strong candidate achieving a slightly higher subject accuracy over all conditions but falls short in its AUC and hence classifying ability yielding more false positives over certain thresholds than the concatenation strategy. The multi-head attention strategy on the other hand being the

worst of the three due to its lower AUC metric and obtaining the lowest coverage rate of 92.5% out of all the fusion strategies. However, it is the top performer in the dim lighting condition by a small margin showing promise of its capabilities.

Feature fusion by concatenation ensures that all extracted information is kept from both modalities which may explain its higher performance over the others. The Hadamard product and multi-head attention strategies tend to mix different aspects from both modalities which may deafen certain characteristics that are relevant for the classification stage. For instance, the element-wise multiplication assumes that the radar feature dimensions correspond exactly with the dimensions of the RGB features which is most certainly never the case since both modalities are represented in separate embedding spaces. Therefore, the pairwise dot strategies, including multi-head attention since this is simply comprising a number of pairwise dot products, aimed to blend all radar features with all RGB features to find all possible correlations to be used by the classification stage. However, it is clear that the subsequent pooling method has a tremendous effect in the effectiveness of the model. For instance, the max-pooling strategy produced the worst performing model in all accounts in many cases performing worse than the individual modalities. The mean and flatten methods had intriguing effects, with the average-pooling producing the highest subject accuracy but a relatively low liveness detection capability. Meanwhile, the flatten method performing relatively well within most tasks just falling shy from the top three. This is interesting since the flatten method aimed to keep all information about the correlations between the two feature vectors much like the concatenation strategy. This suggests that the correlations are not enough to produce rich embeddings. Additionally, following the flatten, the resulting vector is n^2 size meaning that the fused vector is $512^2 = 262,144$ dimensions which likely requires more fully connected layers to compress it into the final 64-dimensional embedding vector.

It is important to note that the AUC metric is invariant to the decision threshold which has a profound impact whenever there is disparity in the cost of false negatives over false positives. In face recognition, especially for secure biometric authentication, false positives indicate a large flaw meaning the model should prioritise minimising them, even if that entails an increase of false negatives which are more tolerable. This is especially true for the binary liveness check. The model should be rewarded for minimising the success rate of 2D spoofing attacks. For this reason, the weighted $F_{0.5}$ scores are more indicative of the models’ real-world applicability.

It is evident from the results of the non-hybrid model using the individual modalities independently, that the RGB embeddings from the pre-trained 2D InsightFace is rich enough to distinguish against real and fake faces at a moderately decent rate. This shows that the subtle pixel-to-pixel differences between the real and fake photographs are effectively extracted and used within the liveness prediction. This can be attributed to the lower quality of the printed faces on paper in comparison to the captures of the live faces. Furthermore, the mmWave radar signatures captured from the Soli are not accurate enough to allow clear separation between the different participants. However, the 3D information from the radar features are effectively leveraged by the

fusion models to boost the relatively low liveness detection capabilities of the RGB-only model.
